ABSTRACT

Atrial fibrillation (AF) is a common cardiac arrhythmia that can be seen in hospitalized patients. It has been shown to be a major risk factor for cardioembolic stroke, and therefore patients are frequently started on lifelong anticoagulation. The majority of patients benefit from either cardioversion or pulmonary vein isolation ablation. We herein describe the case of a 58-year-old male with a past medical history of atrial fibrillation surgery who presented to hospital for elective atrial fibrillation ablation after failed medical therapy and persistent symptoms. A transesophageal echocardiogram (TEE) prior to the procedure demonstrated a left atrial appendage clot despite patient’s compliance with apixiban. Subsequently, the patient is started on warfarin therapy with a heparin bridge. A TEE performed 6 weeks after discharge showed resolution of the left atrial appendage clot allowing the ablation procedure to be successfully performed.

KEY WORDS: Atrial fibrillation; Left atrial appendage thrombus; Novel anticoagulation; Apixiban; Warfarin.

ABBREVIATIONS: TEE: Transesophageal Echocardiogram; AF: Atrial Fibrillation; FXa: Factor Xa; EF: Ejection Fraction; LV: Left Ventricular; ECG: Electrocardiogram; ICE: Intracardiac echocardiogram.

INTRODUCTION

Atrial fibrillation (AF) is the leading cardiac arrhythmia in the United States (US). More than 2.7 million people in the US are known to have AF and this number is expected to rise to 12 million by 2030.1-3 AF accounts for $16-26 billion of annual US expenses.4,5 Stroke is the third most frequent cause of death in US and the leading cause of serious disability; for which AF is a major independent risk factor. It is responsible for 15% of 700,000 strokes occurring in the US each year.6

In AF, the uncoordinated atrial pulse causes pooling of blood in the atrium and more specifically in the left atrial appendage.7 The force of the coordinated atrial contraction can dislodge a thrombus from the left atrial appendage, which then can migrate to the brain causing an ischemic stroke secondary to cardio-embolism.7 The Copenhagen Stroke Study (a prospective, community-based study of 1197 patients with acute stroke) demonstrated that patients with AF had a higher mortality rate (OR, 1.7; 95% CI, 1.2 to 2.5), longer hospital stays (50 days vs. 40 days, p<.001), and a lower discharge rate to their own homes (OR, 0.60; 95% CI, 0.44 to 0.85).8 This study also demonstrated that neurological and functional outcomes were markedly poorer...
in patients with atrial fibrillation due to more severe strokes. Vitamin K antagonists such as warfarin are highly effective in preventing stroke in patients with atrial fibrillation. Warfarin reduces the risk of stroke by two-thirds and mortality by one-quarter compared with control. Warfarin is highly effective in preventing stroke in patients with atrial fibrillation, but has several limitations such as narrow therapeutic window, and drug/food interactions. The limiting factors of warfarin have increased the use of the targeted oral anticoagulants such as Apixiban. Apixiban is direct factor Xa (FXa) inhibitors that prevents FXa from cleaving prothrombin to thrombin.

CASE REPORT

A 58-year-old male with a past medical history of atrial fibrillation (AF), ischemic cardiomyopathy (left ventricular (LV) ejection fraction (EF) of less than 25%), coronary artery disease status post coronary artery bypass graft, aortic stenosis status post bioprosthetic aortic valve replacement, hypertension, hyperlipidemia and obstructive sleep apnea presented pulmonary vein isolation ablation for atrial fibrillation after failed medical therapy and persistent symptoms. The patient initially presented to Pennsylvania Hospital Emergency Department 4 weeks prior with shortness of breath and dyspnea on exertion. He stated that his symptoms had progressively worsened and his electrocardiogram (ECG) revealed that he was in rapid atrial fibrillation. He was subsequently admitted and underwent a transesophageal echocardiogram (TEE) with no visualization of a left atrial appendage thrombus (Figure 1). A direct current cardioversion was performed with restoration of normal sinus rhythm. The patient was started on Apixiban 5 mg twice daily for a CHA$_2$DS$_2$-VASc score of 3 (congestive heart failure, coronary artery disease, and hypertension).

He was seen in follow-up as an outpatient on 2 weeks prior to presentation, where he endorsed symptoms of exertional dyspnea. His ECG showed AF. Although, he reported feeling “much better”, he still had exertional dyspnea, palpitations, and light headedness. He denied chest pain and syncope. After consultation with an electrophysiologist, he was scheduled for an elective AF ablation procedure. At presentation to the hospital, his vital signs were heart rate of 110 beats per minute, blood pressure of 127/78, oxygen saturation of 97% on room air, temperature of 97.9 °F, and respiratory rate of 18 breaths per minute. On physical exam, he was a morbidly obese male in no acute distress, cardiac exam revealed an irregularly irregular rhythm. His lungs were clear to auscultation bilaterally. A TEE was performed prior to atrial fibrillation ablation procedure which demonstrated an EF of 25% with a new left atrial appendage thrombus (Figure 2). Intracardiac echocardiogram (ICE) also confirmed presence of the thrombus, therefore resulting in cancellation of the procedure. The patient was started on a heparin drip and was subsequently bridged to warfarin, with a goal Indian rupee (INR) of 2-3. He was continued on metoprolol 100 mg every 12 hours orally for rate control.

Outcome

Patient was discharged to home on coumadin therapy once his INR was therapeutic. A repeat TEE 4 weeks later showed resolution of the thrombus in left atrium (Figure 3). The patient underwent a successful pulmonary vein isolation ablation on the same day. There were no complications to the procedure and patient was continued on warfarin indefinitely.

DISCUSSION

Our case describes a patient that has failed apixiban therapy for his AF. The Aristotle trial compared apixiban to warfarin and demonstrated that apixiban 5 mg twice daily was superior to warfarin in preventing stroke or systemic embolism. It also caused less bleeding and resulted in lower mortality. On the other hand, some studies have suggested that Apixiban is known to make thrombi mobile and/or fragile, which causes detachment or partial fragmentation of left atrial appendage thrombus that can result in thromboembolism. This is thought to be
secondary to apixiban shifting the coagulation/fibrinolysis balance to a relative predominance of fibrinolytic activity.13-16

Current practice is to have a TEE performed if a patient has been in AF for more than 48 hours to rule out a left atrial thrombus. If a patient has an atrial clot, they are anticoagulated for a duration of 4 weeks. A TEE is performed and if there is resolution of the thrombus, then a cardioversion is performed.17 Current evidence concludes that there does not appear to be a role for routine TEE prior to cardioversion in patients who has been adequately anticoagulated with warfarin or targeted anticoagulant for at least four weeks prior to cardioversion.18 The 2014 AF guidelines classify this recommendation as level C evidence. Seidl et al19 demonstrated that, in patients with AF and effective anticoagulation, TEE-guided electrical cardioversion does not reduce the embolic risk. However, TEE before direct-current cardioversion revealed left atrial thrombus in 7.7% of patients with AF and effective anticoagulation. As this case demonstrates, even four weeks of compliance with anticoagulation with direct acting agents such as apixiban does not completely protect against left atrial thrombus formation, and a pre-cardioversion TEE should be considered in all patients.
