ABSTRACT

Heat treatments are the established food technology for commercial processing of milk. However, degradation of valuable nutrients in milk (as proteins) and its sensory characteristics occur during these processes due to substantial heat exposure. The most important reactions that occur during milk heat treatment are the whey proteins denaturation, its interactions with the casein micelles and aggregation/dissociation of the casein micelles. Microfiltration represents an emerging food processing technology allowing gentle milk preservation at lower temperatures for similar, or better, nutritive value, microbial removal, and shelf stability. Thus, the aim of this work is to review the existing studies on the effects of microfiltration on milk proteins by comparing with the effects of heating treatments.

INTRODUCTION

The proteins are important constituents of the human diet since they are the principal source of nitrogen and essential amino acids. The properties and functionality of the protein depend on its amino acid composition and arrangement of the peptide bonds that stabilize the structure. The functional properties of the proteins are related to various general characteristics such as molecular moisturizing, surface activity and type of protein-protein interactions, facilitated by the partial unfolding of structures. Milk proteins play an important role as functional ingredients in foods, acting as emulsiﬁying, foaming and gelling agents.

Milk is a complex food from a molecular composition perspective which constitutes an important part of a human’s diet, mainly because of its high nutritional value. Milk consists of various protein fractions, such as casein micelles and several whey proteins with different molecular weights. Caseins representing approximately 80% of the total protein fraction in milk. These proteins have excellent surfactant properties in emulsions and foams, gelling properties, and thermal resistance to denaturation because of their lack of complex secondary and tertiary structure. However, the casein micelles are composed of the proteins αS1-, αS2-, β-, and κ-caseins, and salts of Ca, P, Mg, and Zn. In fresh milk, the caseins are present in the form of essentially spherical particles containing many protein molecules and amorphous calcium phosphate; these particles have in average 150 nm of diameter with sizes ranging from 15 to about 1000 nm in diameter. Apart from κ-casein, which is mostly found on/or near the external surface of the micelle, the caseins appear to be more or less evenly distributed within the micelle. Casein micelles are in colloidal suspension in milk and are approximately 100 times larger than whey proteins (0.003 to 0.010 μm), which are soluble in milk. However, the whey proteins are typical globular, highly structured proteins, most of which have been isolated, crystallized, and well characterized. The lactoglobulin fraction contains immunoglobulins G, A, and M, which are present at very high-levels in colostrum and play very important protective roles. The lactalbumin fraction contains two main proteins, α-lactalbumin and β-lactoglobulin, and several minor proteins, including blood serum albumin, lactoferrin, and vitamin-binding proteins; it contains several peptide hormones and about 70 enzymes.
Heat treatment can damage the biological properties of milk components, impair protein availability, and promote intolerance and allergy.\(^5\)\(^,\)\(^6\) It is now well established that high-temperature processing, especially ultra-high temperature (UHT), causes a series of effects on milk such as loss of available lysine,\(^8\)\(^,\)\(^9\) and aggregation and denaturation of protein.\(^10\)\(^-\)\(^13\) As a result, many chemical changes could also occur,\(^14\)\(^-\)\(^16\) in addition to modifications on functional properties of milk proteins.\(^6\) These changes inevitably affect the renneting, emulsifying, and foaming properties of the dairy products based on the processed milk.\(^17\)\(^-\)\(^20\)

The rise of alternative technologies, such as microfiltration, can help prevent these problems while also assuring food safety. Membrane processes are increasingly used in the dairy industry for bacteria removal by microfiltration.\(^21\) Microfiltration (MF) has gained significant attention in recent years as a processing method for the removal of microorganisms from milk.\(^22\)\(^-\)\(^29\) With the advancement of membrane filtration technology, the use in the dairy industry has become more technically and economically feasible.\(^30\)\(^-\)\(^32\) Furthermore, the MF process may preserve the bioavailability of the thermostable and active milk components, such as bioactive peptides, vitamins, and antioxidants. However, works that studied the effects of the microfiltration processes on milk proteins properties are scarce.

Therefore, this work aims to review the existing studies on the effects of milk microfiltration on milk proteins by comparing with the effects of heating treatments, like pasteurization and UHT technology. In other words, our work aims to review the application of milk microfiltration technology to obtain milk with better safety and quality which does not have its original features transformed by thermal processes.

### Proteins Functional Properties

The functionality of food proteins refers to the physical and chemical properties that influence the performance of the proteins of food systems during processing, storage, preparation, and consumption. These characteristics influence the quality and sensory characteristics of food.\(^3\) The functional properties of food proteins can be classified into three main groups: hydration properties, which are dependent on protein-water interactions (water absorption and retention, wettable, swelling, adhesion, dispersibility, solubility and viscosity); properties that are related to protein-protein interactions (precipitation and gelation); and surface properties (surface tension, emulsification and foaming characteristics).\(^3\)

Defining and measuring protein functionality starts at the level of protein structure. A simple model for protein denaturation is:

\[
N \leftrightarrow I \rightarrow D
\]

In this model, a native (N) structure is reversibly converted to an intermediate (I) state where the tertiary structure is changed but much of the secondary structure remains, and further unfolding produces a denatured (D) state. There are various molecular properties associated with each state that have an impact on functional properties (Table 1). According to Foegeding and Davis,\(^3\)\(^6\) molecular weight and primary structure will not be changed during the denaturation process and are considered constants. The isoelectric point can vary due to intermediate and denatured (unfolded) structures exposing charged amino acids to new local environments. The main changes are in a secondary and tertiary structure that can alter the surface exposure of amino acids. This cumulates in an increase in interaction potential, favoring aggregation, and the loss of structural epitopes for allergenicity. Therefore, determining the specific structural transitions during folding/unfolding for food proteins is essential to understand the molecular basis of functionality.\(^3\)

Milk proteins are commonly used as food ingredients in food products not only for their nutritional properties but also for their functional and technological characteristics.\(^3\)\(^5\) Milk proteins have a high nutritional value compared to other proteins, because

of their relatively high content of essential amino acids and better digestibility. Milk consists of various protein fractions: casein micelles (d=50, 3=180 nm, isoelectric point: pH 4.6) and several whey proteins with different molecular weights (d=2-6 nm, isoelectric point: pH~5).

**Casein Functional Properties**

Caseins are one of the most important and complex proteins in milk. These proteins have excellent surfactant properties in emulsions and foams, gelling properties, and thermal resistance to denaturation because of their lack of complex secondary and tertiary structure. However, the casein micelles are composed of four individual gene product component, denoted αS1-, αS2-, β-, and κ-caseins, which differ in primary structure, type and degree of post-translational modification, and salts of Ca, P, Mg, and Zn. The remainder of the micellar solids consists of inorganic material, collectively referred to as colloidal calcium phosphate (CCP) or micellar calcium phosphate (MCP). Casein micelles (0.02 to 0.40 μm in diameter) are in colloidal suspension in milk, and are approximately 100 times larger than whey proteins (0.003 to 0.010 μm), which are soluble in milk.

The internal structure of a casein micelle consists of a protein matrix in which calcium phosphate nanoclusters are dispersed (Figure 1). Attached to the surface of the nanoclusters are the centers of phosphorylation (nearby 3-5 phosphorylated amino acid residues) of the caseins. The tails of the caseins, much larger than the CCP clusters, then associate to form a protein matrix, which can be viewed as polymer mesh. The association of the tails is driven by a collection of hydrophobic interactions (weak interactions). The association is highly cooperative and originates in the weak interactions. It is the cooperative that leads to a stable casein micelle. Invariably, k-casein is thought to limit the process of self-association leading to stabilization of the native casein micelle.

Model Structure of the Casein Micelle Showing a More-or-less Homogenous Protein Matrix Containing Calcium Phosphate Nanocluster-like Particles (•) Distributed with a Mean Spacing of 18 nm. There is No Distinct Hairy Layer, but Rheomorphic Polypeptide Chains Provide Steric Stabilization in the Outermost Limits of the Particle](image)

Caseins exhibit specific interactions with calcium ions and salts. Because of their primary structures and specific tertiary structure, these proteins undergo post-translational phosphorylation. This modification results in the formation of anionic clusters of the calcium-sensitive casein while a single residue is phosphorylated in k-casein, which is insensitive to calcium. The calcium-sensitive caseins, αS1-, αS2- and β-caseins are so called because of its extremely low solubility in the presence of Ca++.

Casein has a long history as essential ingredients for food and due to its open and flexible structure, caseins have different functionality. It can be widely used in several kinds of products. The casein has excellent solubility and thermal stability at pH above 6. Moreover, due to their amphiphilic structure, these proteins are useful for emulsifying, water binding, thickening, creaming/foam, and gel formation. The products based on commercial casein available as food ingredients are acidic casein, casein obtained by enzymatic coagulation, caseinates and coprecipitates. The functionality of these commercial products depends on the type of food in which they are added.

One of the simplest ways to alter the functionality of the proteins is by mild heat treatments that alter protein structure and cause aggregation but do not result in large scale protein precipitation. Denaturation controlled or partial during various isolation steps is generally desirable, as it helps in maintaining an acceptable protein solubility, which is often a prerequisite for the functionality of these proteins in food products.

Proteins are often isolated using isoelectric precipitation. The casein micelles are destabilized irreversibly by isoelectric precipitation. These collapses of the micellar structure of casein are due to several factors, including the solubility of colloidal calcium phosphate and the change in the balance of hydrophobic and electrostatic interactions between different types of casein. The composition of the precipitated proteins usually changed, compared with materials in their native form. These changes at the molecular level may have an impact on protein functionality.

Studies have shown the relationship between the structure of the casein modified by the processing and its functionality. According to Raikos the degree of protein denaturation induced by heat treatment, under the given chemical environment, was concluded to be the key factor which determines the interfacial functionality of milk proteins with subsequent effects on the emulsion properties. In these and other modifications, i.e., Maillard type reactions to form protein/sugar adjuncts, deamidation, enzymatic crosslinking or enzymatic hydrolysis, usually alter the functionality of the protein.

**Whey Proteins Functional Properties**

Whey proteins constitute 20% of the proteins in milk and represent an excellent source of functional proteins of high nutritional value. The most important are the globular proteins β-lactoglobulin (β-LG; approximately 3.2 g/L) and α-lactalbumin.
β-Lactoglobulin is a globular protein with a monomer molecular weight of 18.4 kDa and accounts for about 50% of the protein in bovine whey isolate. The secondary structure is composed of 16% α-helix, 58% β-sheet and 25% random coil.35 Native β-LG has nine strands that are folded into two β-sheets: sheet 1 contains strands B, C and D, and part of strand A (A1); sheet 2 contains strands E, F, G and H, part of strand A (A2) and strand I. One side of sheet 1 is hydrophobic and the other side is hydrophilic. Sheet 2 is also hydrophobic on one side and faces the hydrophobic side of sheet 1, thus creating a very hydrophobic cavity, which is nevertheless filled with water. There is also another hydrophobic region on the side of sheet 2, where the three-turn helix lies above it and along strands F, G and H. β-LG has two disulfide bonds and one free Cys(CysH).43

The α-LA accounts for about 20% the protein in bovine whey, has a molar mass of 14.2 kDa, and is stabilized by four disulfide bonds and does not contain a free thiol group. However, one of the disulfide bonds (Cys6-Cys120) is more sensitive to cleavage than the other three because of its lower inherent stability.44 The protein also exists in a number of environment-dependent conformations, including the holo (native, calcium-bound) form, which is the major form in milk.45

The BSA is a single polypeptide of 582 amino acid residues with a molecular weight of 66,433 Da and exists in a multidomain structure with complex ligand-binding specificities.43 It is characterized by an overall oblate shape and consists of three domains (I, II and III), each stabilized by an internal network of disulfide bonds. The primary structure has 17 disulfide bridges that hold the molecule in a structure consisting of nine loops. It contains one free thiol group, Cys34. The secondary structure is composed of 76% helix, 10% turn, and 23% extended chain, and no β-sheet.2

Whey protein denaturation is one of the main effects of milk heating which causes modification on the chemical and nutritional properties.45 The concentration or isolation of whey protein, which represent excellent functionality and nutritional properties, is economically feasible for use as the basis of many dairy products, cheese, and other protein ingredients.36 Whey protein ingredients are used for a variety of functional applications in the food industry.34,46–48 The milk proteins and particularly whey proteins are commonly used as emulsifying and foaming agents in diverse food products thanks to their unique interfacial properties.49

Unlike the caseins, whey proteins are unstable to heat and this influences the physical and chemical properties of milk products.43 On the other hand, the manufacture of most dairy products involves heat treatment.33 Studies have been conducted on the mechanism of denaturation and aggregation of whey proteins during heating and on ways of preventing such changes which are critical to improving their stability.35

Effects of Heat Treatments on Milk Proteins Structure

Heat treatment of milk and milk products is an essential operation in commercial dairy processes in order to provide acceptable safety and shelf life.50 The most important reactions that occur during milk heat treatment are the whey proteins denaturation, its interactions with the casein micelles and aggregation/dissociation of the casein micelles.31 Denaturation alters several important properties of proteins from the viewpoint of food technology. The denatured protein is generally less soluble or even insoluble, promotes an increase in feed viscosity and the reactivity of their side groups are intensified.2

The denaturation also affects the three-dimensional conformation and functional characteristics of the milk proteins besides the degree of heat denaturation varies depending on the intensity of the thermal treatment applied.35 Changes in protein conformation can affect the thermodynamics of binding with water because they may change the availability of polar sites or hydration sites. The transition from the compact globular conformation of the protein molecule for random conformation can result in an increase of the available surface area and exposure of peptides and amino acid side chains.32

Among the milk proteins, whey proteins are the most thermostable. As been described in the literature, susceptibility of whey proteins to heat denaturation results from their high level of secondary and tertiary structure.35,43,53,54 Because denaturation of whey proteins occurs rapidly at temperatures above 70 °C, commercial heat treatments denature at least a portion of these proteins.35 The functionality of whey proteins is very sensitive to the extent of denaturation. Major whey proteins exhibit thermostability to structural unfolding in the order α-lactalbumin< serum albumin<β-lactoglobulin<immunoglobulin<β-lactoglobulin. However, the thermal unfolding of α-lactalbumin is reversible so that denaturation, as measured by irreversible changes, indicates an order of increasing the thermostability of IgG< serum albumin<β-lactoglobulin<α-lactalbumin.56,57 The thermal behavior of the whey proteins is ruled primarily by the properties of β-lactoglobulin, which are affected by the pH, lactose, sodium chloride, calcium, and other ions.58 In particular, β-lactoglobulin and serum albumin command protein aggregation via thiol-disulfide exchange and oxidation-reduction reactions during the heat treatment.59 Swiss-good report that β-lactoglobulin, are considerably less soluble and more sensitive to precipitation by calcium ions than are their native counterparts when denatured.

The degree of heat denaturation of the whey proteins varies depending on the intensity of the thermal treatment of the milk in during the processing of different products.59 The kinetics of thermal denaturation of whey proteins is complicated, with a significant effect on the ranges between 80-100 °C.60 The dena-
turation reaction shows a non-linear Arrhenius relationship, there is a noticeable change dependent on the temperature around 80-90 °C for both α-LA and β-LG. The apparent activation energy is in the range of 260-280 kJ mol⁻¹ for β-LG and 270-280 kJ mol⁻¹ for the α-LA at temperatures below 90 °C. At higher temperatures the activation energy is lower, ranging from 54 to 60 kJ mol⁻¹ for β-LG and 55 to 70 kJ mol⁻¹ for the α-LA, indicating chemical interactions (aggregation).

Pasteurization or UHT processing causes partial, irreversible unfolding of β-lactoglobulin, thereby exposing hydrophobic surface and the sulfhydryl group. The subsequent interaction with κ-casein, stabilized by a sulfhydryl-disulfide interchange, alters the surface properties of casein micelles (Figure 2). According to Fox1 the κ-casein, in particular, has the ability to react with sulfhydryl group of denatured whey proteins, possibly in these form: [κ-CN]-SH+HS-[β-lactoglobulin]+O₂→[κ-CN]-S-S-[β-lactoglobulin]+H₂O [κ-CN]-SH+SS= [α-La]→[κ-CN]-S-S-[α-La]-SH. These complexes are co-precipitated with caseins when the whey is separated from casein phase, resulting in an increase of the N content and in the size of casein micelles. Therefore, the heat-induced association of whey protein (especially β-lactoglobulin) with casein micelles alters micelle properties and also increases heat stability.63

![Figure 2.](image.png)

On the other hand, the α-lactalbumin does not present SH groups but present four S-S/mol groups. In order to connect α-lactalbumin with the κ-casein, these S-S groups must first be broken by oxygen. Besides being more heat resistant, the functional group of α-lactalbumin is more difficult to connect to the κ-casein, so it is strongly relevant to the thermal stability of milk.63

Oldfield, Singh, and Taylor64 suggested that there are at least three possible kinds of denaturation of β-LG that can associate with the micelles: (i) β-LG monomer unfolded, (ii) self-aggregating β-LG and (iii) aggregate LG β-/α-LA. The relative association rate of these species with the casein micelles depends on the heating gradient, which in turn affect the relative rates of breakdown and formation of different aggregated species. At higher temperatures and faster heating rates, all whey proteins begin to unfold in a very short period of time, thus presenting an opportunity for more monomers of unfolded β-LG to auto aggregate, which in turn could make an association with the caseins micelles less efficiently. These β-LG aggregates could protrude from the surface of the casein micelles promoting a steric effect for new β-LG associations. Furthermore, these aggregates may have their reactive sulfhydryl groups within the array, and thus unavailable for sulfhydryl-disulfide transfer reactions with κ-casein micelle. The formation of β-LG unfolded can be promoted by long periods of heating at low temperature or by heating at a slow rate until the desired temperature. These monomeric molecules of β-LG enter the capillary layer of κ-casein and have easier accessibility to the sulfhydryl group.

Besides time and heating temperature, several other factors influence the extent of association of denatured whey proteins with the casein micelles, which include the pH of the milk prior to heating, the soluble calcium and phosphate concentrations and the concentration of solids in milk.65 According to Swaisgood66 pasteurization (71.7 °C for 15 s) or UHT processing (142-150 °C for 3-6 s) irreversibly increases the amount of colloidal calcium phosphate at the expense of both soluble and ionized calcium and soluble phosphate. Consequently, the pH also decreases, due to the release of protons from primary and secondary phosphates. The calcium transformed in tertiary phosphates. The calcium transformed in tertiary calcium phosphate does not come entirely from the serum because heating also causes dissociation of calcium bound to protein. Thus, pasteurization, and especially sterilization, affects the size distribution of micelles, leading to an increase in the abundance of both large and small micelles. Moreover, heat treatments of increasing severity are accompanied by increased production of dehydroalanine residues, due to β-elimination of disulfide bonds and phosphoseryl residues, increased deamination of asparaginyl and glutaminyl residues, and increased Maillard browning. Cross-linking of protein during heating can result from the reaction of dehydroalanine residues with ε-amino groups of lysyl residues to form lysinoalanine or reaction with sulfhydryl groups of cysteinyln residues to form lantionine.

Due to the growing consumer demands for better retention of the nutritional value, sensory attributes, and longer shelf stability of milk, the emerging technologies processes have become more interesting for the dairy industry.67 One of these emerging technologies that no present the changes in proteins functionality that the heat treatment presents, is the microfiltration process (MF).68 Incorporation of MF in the milk manufacturing process can improve the microbial and sensory quality of milk.69 Moreover, generally enable high flow rates, improve the yield, reduce the processing costs and shown higher quality compared to conventional heat treatments.62
The commercial processing of milk are carried out almost entirely by heating temperature processes.62 Pasteurized milk currently has a short shelf life (about 14 days) due to the presence of remaining bacteria,63 their enzymes,64 and somatic cells67,68 that are not eliminated by this process. On the other hand, UHT treated milk has a longer shelf life, but there is major damage to the molecular structure of milk proteins. It has been reported that heat temperature processes can lead to several changes in milk, including denaturation of whey proteins, the interaction of whey proteins with caseins, inactivation of indigenous enzymes, as well as the destruction of certain nonstarter lactic acid bacteria.22 Therefore, as reported by Elwell and Barbano24 there is a desire in the fluid milk processing industry for an HTST pasteurization process that will produce fluid milk with a refrigerated shelf life of 60 to 90 days. Nevertheless, there are other technologies currently being researched that may eventually replace the pasteurization or the UHT processes.69 These include the membrane filtration process, i.e. microfiltration technologies.70

The microfiltration represent an emerging food processing technology in several countries allowing gentle milk preservation at lower temperatures and shorter treatment times for similar, or better, microbial inactivation and shelf-life stability when applied in a hurdle approach compared to heat temperature processes.62 This process is based on the selective permeability of a membrane for one or more of the constituents of the liquid. Selectivity depends on both the type of membrane (different cut-off) and process conditions.70-72 The liquid submitted to this process is divided into two fractions: the fluid retained by the membrane (i.e., the retentate), which results in a higher concentration of the components having a bigger size than the average pore diameter of the membrane, and the liquid going through the membrane (i.e., the permeate or the microfiltrate) (Figure 3).73

Membrane processes are used to improve the microbial quality of milk and dairy fluids, as well as are also applied for preserving the functional properties of milk proteins.71 Avalli et al73 reported that the mechanic stress of the transmembrane pressure affects minimally the milk proteins in comparison with heat temperature processes. But when the skim milk passes through the microfiltration membrane the proteins and minerals tend to form aggregates in the pores and this problem may decrease the flux and modify its properties and the quantity of the protein in the permeate.80 It has been reported that proteins with low internal stability as β-CN, α-LA, BSA, and immunoglobulin (IgG) tend to adsorb on all surfaces, even onto electrostatically repelling surfaces.81,82 Thus, proteins with diameters much smaller than the membrane pore typically cause pore constriction, while those with a diameter comparable to the membrane pore may cause pore blocking, and proteins larger than the pores can be retained on the membrane surface and cause cake formation.83 Gesan-Guiziou et al84 found that as membrane resistance (fouling) increased, the transmission of whey proteins decreased during the MF of skim milk. On the other hand, another membrane property that needs to be considered is it’s hydrophilic–hydrophobic character because this is known to affect the strength of the interaction between a protein and a surface.78 Specifically, proteins tend to adsorb more extensively and less reversibly at hydrophobic surfaces than at hydrophilic surfaces.85 According to Gao et al,86 ceramic membranes are hydrophilic and this property does not preclude the deposition of proteins onto its surface. As related by Wang et al85 this behavior may occur because whereas proteins tend to unfold and spread their hydrophobic core over hydrophobic surfaces, their charged and polar functional groups...
tend to interact with hydrophilic surfaces. In the case of CN micelles, it is known that the hydrophilic ends of α-CN molecules are preferentially located at the surface of micelles, which would explain the ceramic membrane–CN interactions.\textsuperscript{78}

Investigations on the minor whey protein bovine serum albumin (BSA) conducted by Chandavarkar\textsuperscript{76} and Kim et al\textsuperscript{89} have shown that protein aggregates are formed in shear flow during cross-flow filtration, which is deposited on the membrane surface afterward. In contrast to BSA, the major membrane foulant during whey filtration, β-Lg, is not sensitive to shear forces.\textsuperscript{87} Kelly, Opong, and Zydney,\textsuperscript{86} as well as Kelly and Zydney,\textsuperscript{91} found that BSA-aggregates catalyze fouling when deposited on the membrane. The molecular mechanism involved in the fouling reaction was found to be based on the exposure of reactive thiol-groups in the deposit. This reactive initial deposit then serves as a nucleation site for further thiol oxidation and thiol-interchange reactions. Despite the fact that the proteins varied significantly in size, molecular structure and originated from various animal protein sources (Table 2), Kelly and Zydney\textsuperscript{93} observed that intensity of membrane fouling was correlated to the number of free thiols of the respective protein (Figure 4).

Like as BSA, β-Lg contains one free sulphydryl group (Table 2). Hence, membrane fouling based on thiol-interchange reactions as well as thiol oxidation probably also applies for β-Lg or other whey proteins. This reaction pathway via thiol/disulfide reactions is known for β-Lg aggregation during thermal processing.\textsuperscript{94} Additionally, for the major whey protein β-Lg it was found that gel network formation is facilitated in the presence of calcium.\textsuperscript{95,96} Based on this, Marshall, Munro, and Trägårdh\textsuperscript{97} assumed that calcium-induced cross-linking was involved in β-Lg deposit formation.\textsuperscript{98}

Besides these properties, Kühnl et al\textsuperscript{99} related that the microfiltration flux during cross-flow filtration depends on the pH of milk and showed that the casein micelles where size constant in the pH 5.9-6.8 range. Acidification of milk from pH 6.8 to 5.9 leads to a strong reduction of hydrophilic repulsion between casein micelles while the micelle size remains the same.\textsuperscript{99} In addition to acidification, this behavior can also be described by a model which incorporates van der Waals and electrostatic interactions as well as hydrophilic and hydrophobic Lewis Acid-Base interactions. In accordance, Steinhauer et al\textsuperscript{88} reported that a less repulsion between casein micelles, in turn, results in a flux drop, i.e. that change in colloidal interaction is a basic problem in cross-flow filtration.

In addition, minerals are found in association with casein, whey protein, and fat globule membranes.\textsuperscript{35} Furthermore, the minerals in the whey phase of milk are present as free ions, salts, or in association with whey proteins. According to Swanborg et al\textsuperscript{100} these minerals may pass through the MF membrane, and their distribution after MF fractionation will influence the functional properties of the fractions. For example, the treatment of milk with MF will increase the calcium (Ca) content and the buffering capacity of the retentate, therefore delaying the pH reduction during traditional cheese making.\textsuperscript{101} As reported by Kaombe et al\textsuperscript{102} for pasteurized milk, the temperature of the MF process also may influence the Ca content on dialysates and permeates. On the other hand, even relatively mild heat treatments, such as HTST, could most likely affect the composition and protein yield of the MF permeate. Increasing the temperature is expected to decrease the viscosity of the permeate\textsuperscript{103} and if no change in membrane resistance occurs the transmembrane pressure required to maintain a constant flux is expected to decrease as the temperature is increased.\textsuperscript{104} Moreover, heat denaturation of whey proteins may also change the performance of the membranes during MF.\textsuperscript{106}

Hurt et al\textsuperscript{104} clarified that increasing the temperature of MF from 50 to 65 °C could also cause denaturation of whey proteins and possible association with casein (CN) micelles. Long et al\textsuperscript{105} reported that only 3.4% of β-Lactoglobulin was associated with α-CN after 20 min at 65 °C, and thus when they was covalently associated, the yield of whey protein in the permeate would be reduced. In addition, aggregates of β-LG and α-LA have also been found when heated at 75 °C\textsuperscript{106} being unable to pass through the MF membrane. It was shown that whey protein hydrophobicity increases as a consequence of protein unfolding, e.g. under heat-treatment.\textsuperscript{107} Another reason for protein unfolding and an increase in hydrophobicity is surface denaturation, as it is reported for the adsorption of several proteins including β-LG at hydrophobic surfaces. Unfolding was found to increase when repulsive electrostatic interaction forces were reduced.\textsuperscript{108} It can be assumed that hydrophobic whey protein aggregates can potentially serve as adsorption sites and induce protein unfolding during deposit layer formation on membranes. Steinhauer et al\textsuperscript{109} confirm that β-LG and its heat-induced aggregates are the major...
species made responsible for membrane fouling, forming a high-
ly reactive deposit and accelerate membrane fouling (Figure 4).
Therefore, deposited aggregates serve as nucleation sites for thiol
oxidation and disulfide reactions between deposited particles and
native protein. Some works confirm this theory since aggregates
formed during whey heat-treatment enhance membrane fouling.

Briefly, the microfiltration is an emerging technology
that can improve the quality of milk and dairy products once
that changes in protein properties do not occur as far as in milk
produced by heat treatments. The most important reactions that
occur during milk heat treatment are the protein denaturation of
whey proteins, its interactions with the casein micelles and ag-
gregation/dissociation of the casein micelles. The microfiltration
also has the advantages of retaining spores of microorganisms
and somatic cells that no are affected by heat treatments, that
can damage the milk and dairy products quality and safety. However,
the microfiltration, considerate a mechanical process, makes that
the milk continues to be considered raw and in Brazil (as in other
countries) is not possible to sell raw milk. On the other hand, heat
treatments are the established food technology for commercial
processing of milk in order to provide acceptable safety and shelf
life. The shelf life of pasteurized milk in around 8 days while for
the microfiltered milk is close to 30 days. Finally, how is not
possible yet to produce only microfiltered milk in Brazil, several
works recommend the use of the two technologies (microfiltra-
tion and pasteurization) for preserving the better as is possible
the quality of the milk proteins and the others constituents.

Final Considerations

The microfiltration, a mechanical process, affects minimally the
properties of milk proteins as compared to heat treatments.
However, only the use of membrane filtration process is not
completely understood since the microbiological quality cannot
always be guaranteed, and these may bring some disadvantages to
the consumer. Therefore, more studies regarding the microbi-
ological safety of microfiltered milk must be performed in several
countries. On the other hand, the heat treatment in the fluid milk
technologies is already established in the industry worldwide.
Despite the negative influence on the milk proteins, it is a safer
methodology to produce this kind of products nowadays. The
use of heat treatment prior to microfiltration may induce a higher
membrane fouling because of the formation of protein aggre-
gates. Meanwhile, microfiltration in combination with pasteuriza-
tion can be an alternative to extend the shelf life of pasteurized
milk by removal microorganisms, spores, and somatic cells of
raw milk.

CONFLICTS OF INTEREST

The authors declare that they have no conflicts of interest.
